Abstract

Background Hypospadias is a common congenital malformation. The prevalence of hypospadias has a large geographical variation, and recent studies have reported both increasing and decreasing temporal trends. It is unclear whether hypospadias prevalence is associated with maternal age.

Aim To analyze the prevalence and trends of total hypospadias, isolated hypospadias, hypospadias with multiple congenital anomalies, hypospadias with a known cause,

and hypospadias severity subtypes in Europe over a 10-year period and to investigate whether maternal age is associated with hypospadias.

Methods We included all children with hypospadias born from 2001 to 2010 who were registered in 23 EUROCAT registries. Information on the total number of births and maternal age distribution for the registry population was also provided. We analyzed the total prevalence of hypospadias and relative risks by maternal age.

Results From 2001 to 2010, 10,929 hypospadias cases were registered in 5,871,855 births, yielding a total prevalence of 18.61 per 10,000 births. Prevalence varied considerably between different registries, probably due to differences in ascertainment of hypospadias cases. No significant temporal trends were observed with the exceptions of an increasing trend for anterior and posterior hypospadias and a decreasing trend for unspecified hypospadias. After adjusting for registry effects, maternal age was not significantly associated with hypospadias.

Conclusions Total hypospadias prevalence was stable in 23 EUROCAT registries from 2001 to 2010 and was not significantly influenced by maternal age.

Introduction

Hypospadias is one of the most common congenital malformations. Hypospadias is often classified into anterior hypospadias: the urethral opening is slightly displaced but still in the glandular or subcoronal region; middle hypospadias: the urethra opens into the ventral surface of the penis;

and posterior hypospadias: the urethral opening is located in the penoscrotal junction, scrotum, or perineum [1]. The severity of hypospadias is not only explained by the urethral location, as many other factors (e.g., level of division of the corpus spongiosum, size of the glans, and degree of ventral penile hypoplasia) play a role [2]. Hypospadias may be associated with chordee, cryptorchidism, and other urogenital anomalies. Most patients with hypospadias require surgical correction, but medical, social, and sexual problems may persist after surgery [3].

The etiology of hypospadias is largely unknown. Some hypospadias are monogenetic in origin, but the vast majority of cases seem to be multifactorial with many genetic and environmental factors playing a role [4, 5]. One study found a higher incidence of hypospadias in offspring of vegetarian mothers [6]. However, while several environmental exposures and maternal factors have been studied, only low birth weight, maternal hypertension, pre-eclampsia, and maternal intrauterine diethylstilbestrol exposure have been consistently associated with hypospadias [5]. The association between hypospadias and increased maternal age and exposure to endocrine disrupting chemicals remains controversial [4, 5, 7].

The prevalence of hypospadias shows large geographical variation, ranging from 2.0 to 43.2 cases per 10,000 births [8–10]. It is unclear whether hypospadias prevalence is rising. Early studies reported increasing prevalence [8,

[11, 12], while later studies reported increasing [10, 13–15], stable, or decreasing prevalence [16–18]. The varying prevalence and trends might be explained by genetic or environmental risk factors that differ between geographical regions and which increase or decrease locally over time. However, another explanation is methodological differences between studies, i.e., ascertainment of hypospadias cases may vary, and glandular hypospadias and hypospadias with known etiology might be excluded from some studies, explaining the lower prevalence in some regions. Moreover, data on the severity of the hypospadias cases are often unavailable.

In this study, we analyzed the prevalence and trends of total hypospadias, isolated hypospadias, hypospadias with multiple congenital anomalies (MCA), hypospadias with a known cause, and hypospadias severity subtypes in 23 EUROCAT registries from 2001 to 2010. We also investigated whether maternal age was associated with hypospadias prevalence. Our study is the largest of its kind in Europe.

Patients and methods

Patient population

EUROCAT registries are population-based, registering data on congenital anomalies in live births, fetal deaths from 20 weeks of gestational age and terminations of pregnancy for fetal anomalies [19]. Cases are actively ascertained from multiple sources, but ascertainment varies considerably due to differences in the data sources that are accessible to individual registries [20]. Of the 31 EUROCAT full member registries, 23 provided data for this study (Table 1; 5,871,855 births covered). The total births covered per year varied from 3040 in Mainz to 100,360 in Hungary.

All participating registries completed a questionnaire concerning their inclusion and ascertainment of hypospadias cases from 2001 to 2010. In 1980, EUROCAT guidelines specified that cases with glandular hypospadias should only be registered if occurring in combination with other major structural malformations [21]. The exclusion of this minor form of hypospadias was to be applied locally. However, Dolk et al. [16] found that some registries were not able to apply the exclusion guideline. In order to ensure consistency and standardization of coding between registries, the exclusion was lifted, and from January 1, 2005, glandular hypospadias cases were included [22].

For this study, data were extracted from the EUROCAT central database in April 2013 for the years 2001–2010. Total hypospadias prevalence rates were calculated as the total number of hypospadias cases divided by the total

number of births (male and female) in the population covered by the registry. Hypospadias cases were coded by International Classification of Diseases (ICD) British Pediatric Association; ICD9, codes 7526.01–7526.04 (specified subtypes) and 7526.09 (not otherwise specified, NOS) and ICD10, codes Q54.0–Q54.3 (specified subtypes) and Q54.9 (NOS). Registries were asked to specify all cases with ‘other’ hypospadias (ICD10 code Q54.8, $n = 68$), which led to a better classification in the majority of cases ($n = 48$). The remaining 20 ‘other’ hypospadias cases were excluded from the analyses because of unconfirmed diagnosis. Hypospadias was categorized as isolated cases, MCA cases and cases with a known cause using the EUROCAT MCA algorithm [23]. In isolated cases, no other major structural malformation is present. In MCA cases, hypospadias is seen in combination with at least one unrelated major structural malformation that cannot be explained by an underlying syndrome or sequence. In cases with a known cause, the hypospadias has a chromosomal, genetic, or teratogenic origin. All MCA cases were manually reviewed by the EUROCAT Coding and Classification committee or by a clinical geneticist (JEH Bergman). In two hypospadias cases, the etiology could not be classified after manual review and those cases were excluded.

For the maternal age analyses, we calculated hypospadias prevalence rates within six maternal age groups (Table 2). Hypospadias cases with unknown maternal age (1.5 %) were excluded from the maternal age analyses. Wessex (UK), Hungary, and Isle de la Reunion were excluded as maternal age was missing for >20 % of hypospadias cases or they could not provide maternal age denominators for the population covered by their registry.

Statistical analysis

Change in the annual prevalence rates over time was assessed by the χ^2 test for trend and heterogeneity. Results were classified as follows:

- No significant change in prevalence over time: $p \geq 0.05$ for both linear and nonlinear components;
- Significant increasing or decreasing trend: $p < 0.05$ for trend and $p \geq 0.01$ for nonlinear change, or $p < 0.01$ for both trend and nonlinear change, and the trend is monotonic;
- Significant heterogeneous in time: $p < 0.05$ for nonlinear change and $p > 0.05$ for trend, or $p < 0.01$ for nonlinear change and $p \geq 0.01$ for trend.

Multilevel Poisson regression analysis was performed using generalized estimating equations (GEE) to take into account the dependency of cases within registries. In the

GEE, the number of cases was corrected for the number of births with year of birth as the predictor.

A Poisson regression model using STATA version 12.1 was used to derive maternal age-specific relative risks (RR) relative to the 25- to 29-year age group baseline. A model for all cases of hypospadias adjusting for registry was fitted to adjust for the possibility that registries with high proportions of mothers in any one age group would bias the RR estimates between age groups.

Results

Registration policy

Only four of the 23 participating registries were able to adhere to the original EUROCAT guideline to exclude isolated glandular hypospadias prior to 2005 (Table 1). Fifteen registries had registered all hypospadias subtypes (including glandular hypospadias) from 2001 to 2010, and four registries used different criteria for the registration of hypospadias (Table 1). None of the registries reported a change in case ascertainment specific to hypospadias over the study period. However, case ascertainment in Dublin was affected by data protection issues, and Emilia Romagna increased general ascertainment by adding additional information sources since 2003 and including cases up to 1 year of age (instead of 1 week of age) in 2010. Almost all registries believed that their ascertainment of glandular hypospadias was incomplete, because these cases are not always notified to the registry or they are not diagnosed soon after birth and therefore missed in registries that only have data from the neonatal period. Only Mainz believed that their ascertainment of hypospadias cases was complete, since every newborn is examined by registry pediatricians. Northern Netherlands requires parental consent to register cases, which has been constant at 80 % from 2001 to 2010. Since 2010, the registry also records the diagnosis of cases whose parents did not respond to repeated letters asking for consent. Specification of hypospadias subtype varied considerably between registries, with the percentage of unspecified cases varying between 3.8 and 87.4 %.

Prevalence and trends over time

A total of 10,929 hypospadias cases were registered among 5,871,855 births covered by 23 EUROCAT

registries from 2001 to 2010, yielding a total prevalence of 18.61 per 10,000 births (Table 1). Prevalence varied considerably per registry, from 5.10 in South Portugal to 36.83 per 10,000 births in Mainz. Total hypospadias prevalence was stable from 2001 to 2010 (p value trend = 0.136), but the data were heterogeneous over time ($p = 0.013$) (Fig. 1a). Multilevel Poisson regression analysis confirmed the heterogeneity between registries ($p < 0.001$) but did not show a significant year-of-birth effect (Fig. 1a).

Trend analyses for individual registries showed increasing trends in nine registries, decreasing trends in five registries, heterogeneity over time in four registries, and no significant change in prevalence in five registries (Table 1). Of the four registries that excluded glandular hypospadias following the original EUROCAT coding guideline [21], two had a significant increasing trend, and two were significantly heterogeneous over time (Table 1). In the four EUROCAT registries with the highest hypospadias prevalence, no increasing trend was seen (Table 1).

The majority of hypospadias cases was isolated ($n = 9667$; 88.5 %), 9.6 % were MCA ($n = 1053$), and only 1.9 % of cases had hypospadias with a chromosomal ($n = 112$), genetic ($n = 86$), or teratogenic origin ($n = 11$). There was no significant trend for any of these groups (Fig. 1b).

Hypospadias subtypes were specified in 45.6 % of cases ($n = 4980$); 31.5 % had anterior hypospadias ($n = 3443$); 10.2 % had middle hypospadias ($n = 1109$); and 3.9 % had posterior hypospadias ($n = 428$). For hypospadias NOS, a significant decreasing trend was observed ($p < 0.001$), whereas anterior and posterior hypospadias showed a significant increasing trend ($p < 0.001$ and $p = 0.005$, respectively) (Fig. 1c). Middle hypospadias showed heterogeneous data over time ($p = 0.001$) (Fig. 1c).

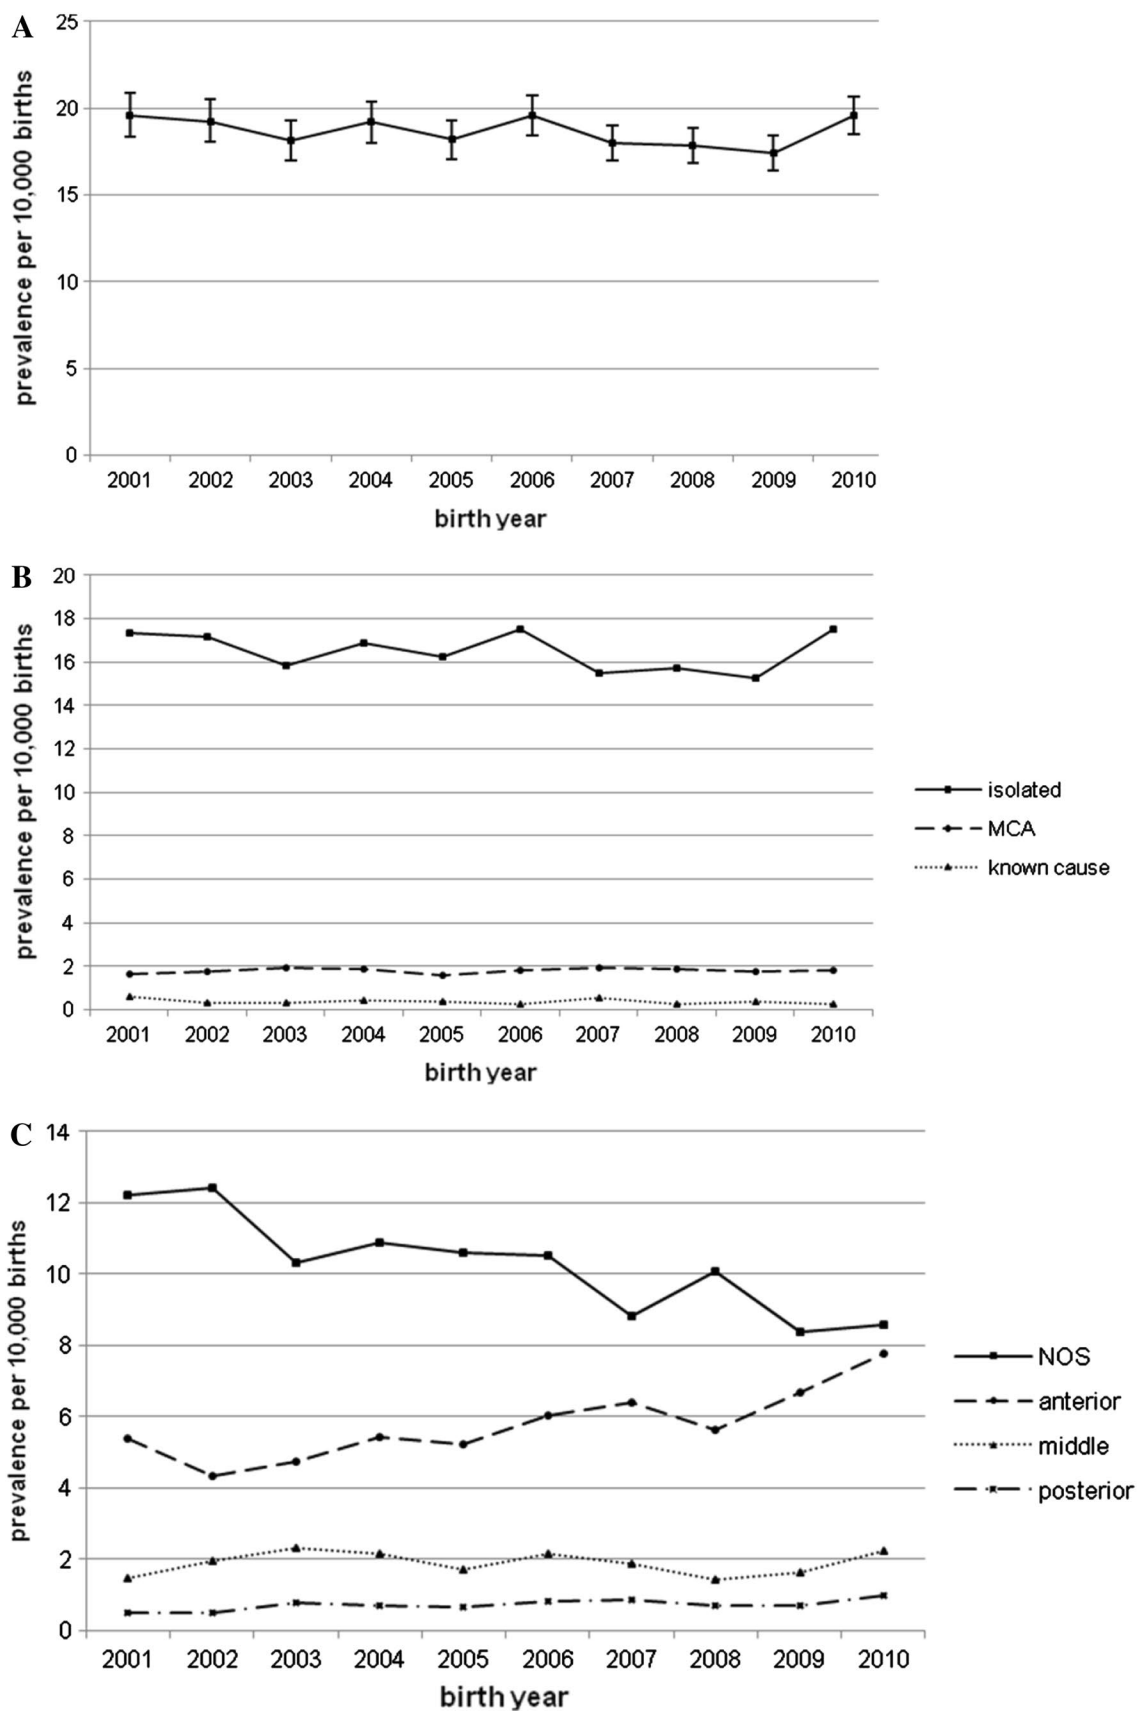

Maternal age and hypospadias prevalence

In this study, teenage mothers had a higher prevalence of total hypospadias compared to mothers aged 25–29 years (unadjusted RR 1.13, 95 % confidence interval (CI) 1.02–1.26, Table 2). This association remained when analyses were repeated excluding chromosomal anomalies. However, after adjustment for registry effects, the increased hypospadias risk in young mothers was no longer significant (adjusted RR 1.12, 95 % CI 1.00–1.24, $p = 0.051$, Table 2).

Discussion

In this large European study, with more than 5.8 million births covered by 23 EUROCAT registries, we found a total hypospadias prevalence of 18.61 per 10,000 births that was stable from 2001 to 2010. Hypospadias prevalence and trends are influenced by the registration policies of the individual registries, as is apparent from the large variations in prevalence and trends per registry (Table 1). This could explain the stable prevalence over time found in this study compared to a previous EUROCAT study reporting an increasing trend over the years 1999–2008 using data from partly overlapping registries [14]. Whether glandular hypospadias is registered or not will have a large effect on total hypospadias prevalence because anterior hypospadias is by far the most common [10, 13]. Ascertainment of hypospadias is incomplete in

some registries, and this has a large effect on the prevalence of hypospadias, thus hindering the evaluation of trends. Ascertainment depends on the sources of information that registries can access (e.g., if only surgical data are available, mild cases can be missed), how cases are notified to the registry (active versus passive notification), jurisdiction (data protection issues), differences in diagnostic methods, screening or treatment per country (mild cases might not be diagnosed), and variation in the follow-up period of cases (when follow-up is short, mild hypospadias may not yet have been diagnosed, or a preputial anomaly can be misdiagnosed as hypospadias) [7, 16, 24, 25]. The low hypospadias prevalence in South Portugal (5.10/10,000 births) is largely due to incomplete ascertainment, as ascertainment of all congenital anomalies is low in this registry [26]. The lack of an increasing trend in hypospadias prevalence over all EUROCAT registries combined, as well as in the four EUROCAT registries with the highest prevalence, and therefore probably the best ascertainment, is reassuring.

More reliable prevalence rates and trends can be ascertained by systematically performing standardized examination of complete birth cohorts, as was done in Rotterdam for hypospadias [25] and is routinely done by the Mainz registry. In Rotterdam, a hypospadias prevalence of 38 per 10,000 live births was seen from 1998 to 2000 [25], very similar to the total prevalence of 36.83 per 10,000 births found in Mainz from 2001 to 2010. The main drawbacks of this approach are that the population size is invariably small, only a very limited region is covered, and it is more expensive to conduct.

Although environmental factors are known to contribute to the etiology of hypospadias [4, 5], their role in isolated or MCA hypospadias is largely unknown [18]. In this study, no trends over time were seen in isolated or MCA hypospadias.

Table 2 Total hypospadias prevalence and relative risk estimates per maternal age category in 20 EUROCAT registries in 2001–2010

Maternal age category (years)	Number of hypospadias cases	Number of births	Total hypospadias prevalence per 10,000 births (95 % CI)	Unadjusted Relative Risk (95 % CI)	Relative Risk adjusted by registry (95 % CI)

CI confidence interval

Data from Isle de la Reunion, Wessex (UK), and Hungary were excluded. In addition, cases with unknown maternal age ($n = 117$ among 20 registries) were also excluded from maternal age analyses

* p value = 0.051

Hypospadias cases were also classified according to severity: anterior, middle, or posterior hypospadias. Unfortunately, the severity was known in less than half of hypospadias cases, making interpretation of trends difficult. It is possible that the increasing trends in anterior and posterior subtypes found in this study could be explained by the decreasing trend in hypospadias NOS, as EUROCAT efforts to improve and standardize coding led to better specification of hypospadias by some registries over time.

Increased maternal age has been found to be associated with higher risk of hypospadias in some studies [17, 27, 28], but not in others [15, 29, 30]. In this study, hypospadias prevalence did not differ significantly between the maternal age groups after adjustment for registry, but the highest hypospadias prevalence was seen in teenage mothers and not in older mothers.

This study shows both the advantages and disadvantages of using birth defect registry data to investigate prevalence and trends in hypospadias. While the introduction of new EUROCAT coding guidelines in 2005 was intended to standardize registration, further efforts are needed to implement guidelines locally. We recommend better specification of cases and increased ascertainment where possible. Combining data from birth defects registries with smaller studies that can guarantee complete case ascertainment and classification will provide optimal information about prevalence and trends of hypospadias.

Acknowledgments This study is a part of the EUROCAT Joint Action funded by the European Commission, under the framework of European Union Health Program 2008–2013, Grant Agreement 20102204 (Executive Agency for Health and Consumers). EUROCAT registries are funded as described by Greenlees et al. [20]. EUROCAT Northern Netherlands is funded by the Dutch Ministry of Welfare, Health and Sports. We thank all the people throughout Europe who are involved in providing and processing information, including affected families, clinicians, health professionals, medical record clerks, and registry staff. We thank Henk Groen for performing the GEE analysis and Kate Mc Intyre for editorial assistance.

Conflict of interest The authors declare that they have no conflicts of interest.

Ethical standard This study was done with anonymized patient data, and therefore, ethics committee approval was not necessary.
